[57] ABSTRACT

Adaptive compressive gain and level dependent spectral shaping circuitry for a hearing aid include a microphone to produce an input signal and a plurality of channels connected to a common circuit output. Each channel has a preset frequency response. Each channel includes a filter with a preset frequency response to receive the input signal and to produce a filtered signal, a channel amplifier to amplify the filtered signal to produce a channel output signal, a threshold register to establish a channel threshold level, and a gain circuit. The gain circuit increases the gain of the channel amplifier when the channel output signal falls below the channel threshold level and decreases the gain of the channel amplifier when the channel output signal rises above the channel threshold level. A transducer produces sound in response to the signal passed by the common circuit output.

BACKGROUND OF THE INVENTION

The present invention relates to adaptive compressive gain and level dependent spectral shaping circuitry for a sound reproduction system and, more particularly, to such circuitry for a hearing aid.

The ability to perceive speech and other sounds over a wide dynamic range is important for employment and daily activities. When a hearing impairment limits a person's dynamic range of perceptible sound, incoming sound falling outside of the person's dynamic range should be modified to fall within the limited dynamic range to be heard. Soft sounds fall outside the limited dynamic range of many hearing impairments and must be amplified above the person's hearing threshold with a hearing aid to be heard. Loud sounds fall within the limited dynamic range of many hearing impairments and do not require a hearing aid or amplification to be heard. If the gain of the hearing aid is set high enough to enable perception of soft sounds; however, intermediate and loud sounds will be uncomfortably loud. Because speech recognition does not increase over that obtained at more comfortable levels, the hearing-impaired person will prefer a lower gain for the hearing aid. However, a lower gain reduces the likelihood that soft sounds will be amplified above the hearing threshold. Modifying the operation of a hearing aid to reproduce the incoming sound at a reduced dynamic range is referred to herein as compression.

It has also been found that the hearing-impaired prefer a hearing aid which varies the frequency response in addition to the gain as sound level increases. The hearing-impaired may prefer a first frequency response and a high gain for low sound levels, a second frequency response and an intermediate gain for intermediate sound levels, and a third frequency response and a low gain for high sound levels. This operation of a hearing aid to vary the frequency response and the gain as a function of the level of the incoming sound is referred to herein as "level dependent spectral shaping."

In addition to amplifying and filtering incoming sound effectively, a practical ear-level hearing aid design must accommodate the power, size and microphone placement limitations dictated by current commercial hearing aid designs. While powerful digital signal processing techniques are available, they can require considerable space and power

so that most are not suitable for use in an ear-level hearing aid. Accordingly, there is a need for a hearing aid that varies its gain and frequency response as a function of the level of incoming sound, i.e., that provides an adaptive compressive gain feature and a level dependent spectral shaping feature each of which operates using a modest number of computations, and thus allows for the customization of variable gain and variable filter parameters according to a user's preferences.

SUMMARY OF THE INVENTION

Among the several objects of the present invention may be noted the provision of a circuit in which the gain is varied in response to the level of an incoming signal; the provision of a circuit in which the frequency response is varied in response to the level of an incoming signal; the provision of a circuit which adaptively compresses an incoming signal occurring over a wide dynamic range into a limited dynamic range according to a user's preference; the provision of a circuit in which the gain and the frequency response are varied in response to the level of an incoming signal; and the provision of a circuit which is small in size and which has minimal power requirements for use in a hearing aid.

Generally, in one form the invention provides an adaptive compressing and filtering circuit having a plurality of channels connected to a common output. Each channel includes a filter with preset parameters to receive an input signal and to produce a filtered signal, a channel amplifier which responds to the filtered signal to produce a channel output signal, a threshold circuit to establish a channel threshold level for the channel output signal, and a gain circuit. The gain circuit responds to the channel output signal and the channel threshold level to increase the gain setting of the channel amplifier up to a predetermined limit when the channel output signal falls below the channel threshold level and to decrease the gain setting of the channel amplifier when the channel output signal rises above the channel threshold level. The channel output signals are combined to produce an adaptively compressed and filtered output signal. The circuit is particularly useful when incorporated in a hearing aid. The circuit would include a microphone to produce the input signal and a transducer to produce sound as a function of the adaptively compressed and filtered output signal. The circuit could also include a second amplifier in each channel which responds to the filtered signal to produce a second channel output signal. The hearing aid may additionally include a circuit for programming the gain setting of the second channel amplifier as a function of the gain setting of the first channel amplifier.

Another form of the invention is an adaptive gain amplifier circuit having an amplifier to receive an input signal in the audible frequency range and to produce an output signal. The circuit includes a threshold circuit to establish a threshold level for the output signal. The circuit further includes a gain circuit which responds to the output signal and the threshold level to increase the gain of the amplifier up to a predetermined limit in increments having a magnitude d_p when the output signal falls below the threshold level and to decrease the gain of the amplifier in decrements having a magnitude d_m when the output signal rises above the threshold level. The output signal is compressed as a function of the ratio of d_m over d_p to produce an adaptively compressed output signal. The circuit is particularly useful in a hearing aid. The circuit may include a microphone to produce the input signal and a transducer to produce sound as a function of the adaptively compressed output signal.

Still another form of the invention is a programmable compressive gain amplifier circuit having a first amplifier to

receive an input signal in the audible frequency range and to produce an amplified signal. The circuit includes a threshold circuit to establish a threshold level for the amplified signal. The circuit further includes a gain circuit which responds to the amplified signal and the threshold level to increase the gain setting of the first amplifier up to a predetermined limit when the amplified signal falls below the threshold level and to decrease the gain setting of the first amplifier when the amplified signal rises above the threshold level. The amplified signal is thereby compressed. The circuit also has a second amplifier to receive the input signal and to produce an output signal. The circuit also has a gain circuit to program the gain setting of the second amplifier as a function of the gain setting of the first amplifier. The output signal is programmably compressed. The circuit is useful in a hearing aid. The circuit may include a microphone to produce the input signal and a transducer to produce sound as a function of the programmably compressed output signal.

Still another form of the invention is an adaptive filtering circuit having a plurality of channels connected to a common output, each channel including a filter with preset parameters to receive an input signal in the audible frequency range to produce a filtered signal and an amplifier which responds to the filtered signal to produce a channel output signal. The circuit includes a second filter with preset parameters which responds to the input signal to produce a characteristic signal. The circuit further includes a detector which responds to the characteristic signal to produce a control signal. The time constant of the detector is programmable. The circuit also has a log circuit which responds to the detector to produce a log value representative of the control signal. The circuit also has a memory to store a preselected table of log values and gain values. The memory responds to the log circuit to select a gain value for each of the amplifiers in the channels as a function of the produced log value. Each of the amplifiers in the channels responds to the memory to separately vary the gain of the respective amplifier as a function of the respective selected gain value. The channel output signals are combined to produce an adaptively filtered output signal. The circuit is useful in a hearing aid. The circuit may include a microphone to produce the input signal and a transducer to produce sound as a function of the adaptively filtered output signal.

Yet still another form of the invention is an adaptive filtering circuit having a filter with variable parameters to receive an input signal in the audible frequency range and to produce an adaptively filtered signal. The circuit includes an amplifier to receive the adaptively filtered signal and to produce an adaptively filtered output signal. The circuit additionally has a detector to detect a characteristic of the input signal and a controller which responds to the detector to vary the parameters of the variable filter and to vary the gain of the amplifier as functions of the detected characteristic.

Other objects and features will be in part apparent and in part pointed out hereinafter.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a block diagram of an adaptive compressive gain circuit of the present invention.

FIG. 2 is a block diagram of an adaptive compressive gain circuit of the present invention wherein the compression ratio is programmable.

FIG. 3 is a graph showing the input/output curves for the circuit of FIG. 2 using compression ratios ranging from 0-2.

FIG. 4 shows a four channel level dependent spectral shaping circuit wherein the gain in each channel is adaptively compressed using the circuit of FIG. 1.

FIG. 5 shows a four channel level dependent spectral shaping circuit wherein the gain in each channel is adaptively compressed with a programmable compression ratio using the circuit of FIG. 2.

FIG. 6 shows a four channel level dependant spectral shaping circuit wherein the gain in each channel is adaptively varied with a level detector and a memory.

FIG. 7 shows a level dependant spectral shaping circuit wherein the gain of the amplifier and the parameters of the filters are adaptively varied with a level detector and a memory.

FIG. 8 shows a two channel version of the four channel circuit shown in FIG. 6.

FIG. 9 shows the output curves for the control lines leading from the memory of FIG. 8 for controlling the amplifiers of FIG. 8.

DETAILED DESCRIPTION OF PREFERRED EMBODIMENTS

An adaptive filtering circuit of the present invention as it would be embodied in a hearing aid is generally indicated at reference number 10 in FIG. 1. Circuit 10 has an input 12 which represents any conventional source of an input signal such as a microphone, signal processor, or the like. Input 12 also includes an analog to digital converter (not shown) for analog input signals if circuit 10 is implemented with digital components. Likewise, input 12 includes a digital to analog converter (not shown) for digital input signals if circuit 10 is implemented with analog components.

Input 12 is connected by a line 14 to an amplifier 16. The gain of amplifier 16 is controlled via a line 18 by an amplifier 20. Amplifier 20 amplifies the value stored in a gain register 24 according to a predetermined gain setting stored in a gain register 22 to produce an output signal for controlling the gain of amplifier 16. The output signal of amplifier 16 is connected by a line 28 to a limiter 26. Limiter 26 peak clips the output signal from amplifier 16 to provide an adaptively clipped and compressed output signal at output 30 in accordance with the invention, as more fully described below. The output 30, as with all of the output terminals identified in the remaining Figs. below, may be connected to further signal processors or to drive the transducer (not shown) of a hearing aid.

With respect to the remaining components in circuit 10, a comparator 32 monitors the output signal from amplifier 16 via line 28. Comparator 32 compares the level of said output with a threshold level stored in a register 34 and outputs a comparison signal via a line 36 to a multiplexer 38. When the level of the output signal of amplifier 16 exceeds the threshold level stored in register 34, comparator 32 outputs a high signal via line 36. When the level of the output of amplifier 16 falls below the threshold level stored in register 34, comparator 32 outputs a low signal via line 36. Multiplexer 38 is also connected to a register 40 which stores a magnitude dp and to a register 42 which stores a magnitude dm. When multiplexer 38 receives a high signal via line 36, multiplexer 38 outputs a negative value corresponding to dm via a line 44. When multiplexer 38 receives a low signal via line 36, multiplexer 38 outputs a positive value corresponding to dp via line 44. An adder 46 is connected via line 44 to multiplexer 38 and is connected via a line 54 to gain register 24. Adder 46 adds the value output by multiplexer 38 to the value stored in gain register 24 and outputs the sum

via a line 48 to update gain register 24. The circuit components for updating gain register 24 are enabled in response to a predetermined portion of a timing sequence produced by a clock 50. Gain register 24 is connected by a line 52 to amplifier 20. The values stored in registers 22 and 24 thereby control the gain of amplifier 20. The output signal from amplifier 20 is connected to amplifier 16 for increasing the gain of amplifier 16 up to a predetermined limit when the output level from amplifier 16 falls below the threshold level stored in register 34 and for decreasing the gain of amplifier 16 when the output level from amplifier 16 rises above the threshold level stored in register 34.

In one preferred embodiment, gain register 24 is a 12 bit register. The six most significant bits are connected by line 52 to control the gain of amplifier 16. The six least significant bits are updated by adder 46 via line 48 during the enabling portion of the timing sequence from clock 50. The new values stored in the six least significant bits are passed back to adder 46 via line 54. Adder 46 updates the values by dm or dp under the control of multiplexer 38. When the six least significant bits overflow the first six bits of gain register 24, a carry bit is applied to the seventh bit of gain register 24, thereby incrementing the gain setting of amplifier 20 by one bit. Likewise, when the six least significant bits underflow the first six bits of gain register 24, the gain setting of amplifier 20 is decremented one bit. Because the magnitudes dp and dm are stored in log units, the gain of amplifier 16 is increased and decreased by a constant percentage. A one bit change in the six most significant bits of gain register 24 corresponds to a gain change in amplifier 16 of approximately $\frac{1}{4}$ dB. Accordingly, the six most significant bits in gain register 24 provide a range of 32 decibels over which the conditions of adaptive limiting occur.

The sizes of magnitudes dp and dm are small relative to the value corresponding to the six least significant bits in gain register 24. Accordingly, there must be a net contribution of positive values corresponding to dp in order to raise the six least significant bits to their full count, thereby incrementing the next most significant bit in gain register 24. Likewise, there must be a net contribution of negative values corresponding to dm in order for the six least significant bits in gain register 24 to decrement the next most significant bit in gain register 24. The increments and decrements are applied as fractional values to gain register 24 which provides an averaging process and reduces the variance of the mean of the gain of amplifier 16. Further, since a statistical average of the percent clipping is the objective, it is not necessary to examine each sample. If the signal from input 12 is in digital form, clock 50 can operate at a frequency well below the sampling frequency of the input signal. This yields a smaller representative number of samples. For example, the sampling frequency of the input signal is divided by 512 in setting the frequency for clock 50 in FIG. 1.

In operation, circuit 10 adaptively adjusts the channel gain of amplifier 16 so that a constant percentage clipping by limiter 26 is achieved over a range of levels of the signal from input 12. Assuming the input signal follows a Laplacian distribution, it is modeled mathematically with the equation:

$$p(x) = 1/(\sqrt{2}R) e^{-(\sqrt{2}x)/R} \quad (1)$$

In equation (1), R represents the overall root mean square signal level of speech. A variable F_L is now defined as the fraction of speech samples that fall outside of the limits (L , $-L$). By integrating the Laplacian distribution over the intervals $(-\infty, -L)$ and $(L, +\infty)$, the following equation for F_L is derived:

$$F_L = e^{-(\sqrt{2}(L/R))} \quad (2)$$

As above, when a sample of the signal from input 12 is in the limit set by register 34, the gain setting in gain register 24 is reduced by dm. When a sample of the signal from input 12 is not in limit, the gain is increased by dp. Therefore, circuit 10 will adjust the gain of amplifier 16 until the following condition is met:

$$(1-F_L)dp = F_Ldm \quad (3)$$

After adaption, the following relationships are found:

$$dp = F_L(dp + dm) \quad (4)$$

$$R/L = \sqrt{2}/\ln(1+dm/dp) \quad (5)$$

Within the above equations, the ratio R/L represents a compression factor established by the ratio dm/dp. The percentage of samples that are clipped at $\pm L$ is given by:

$$\% \text{ clipping} = F_L * 100 \quad (6)$$

Table I gives typical values that have been found useful in a hearing aid. Column three is the "headroom" in decibels between the root mean square signal value of the input signal and limiting.

TABLE I

	dm/dp	R/L	R/L in dB	% clipping
0		∞	∞	100
$\frac{1}{16}$		23.3	27.4	94
$\frac{1}{8}$		12.0	21.6	89
$\frac{1}{4}$		6.3	16.0	80
$\frac{1}{2}$		3.5	10.9	67
1		2.04	6.2	50
2		1.29	2.2	33
4		.88	-1.1	20
8		.64	-3.8	11
16		.50	-6.0	6
32		.40	-7.9	3

In the above equations, the relationship $R=G\sigma$, applies where G represents the gain prior to limiting and σ represents the root mean square speech signal level of the input signal. When the signal level σ changes, circuit 10 will adapt to a new state such that R/L or $G\sigma/L$ returns to the compression factor determined by dp and dm. The initial rate of adaption is determined from the following equation:

$$dg/dt = f_c(dp(1-e^{-(\sqrt{2}(L/G\sigma))})-dm(e^{-(\sqrt{2}(L/G\sigma))})) \quad (7)$$

In equation (7), f_c represents the clock rate of clock 50. The path followed by the gain (G) is determined by solving the following equations recursively:

$$dG = dp(1-e^{-(\sqrt{2}(L/G\sigma))})-dm(e^{-(\sqrt{2}(L/G\sigma))}) \quad (8)$$

$$G = G + dG \quad (9)$$

Within equations (8) and (9), the attack and release times for circuit 10 are symmetric only for a compression factor (R/L) of 2.04. The attack time corresponds to the reduction of gain in response to an increase in signal σ . Release time corresponds to the increase in gain after the signal level σ is reduced. For a compression factor setting of 12, the release time is much shorter than the attack time. For a compression factor setting of 0.64 and 0.50, the attack time is much shorter than the release time. These latter values are preferable for a hearing aid.

As seen above, the rate of adaption depends on the magnitudes of dp and dm which are stored in registers 40

and 42. These 6-bit registers have a range from $\frac{1}{128}$ dB to $\frac{63}{128}$ (dB). Therefore, at a sampling rate of 16 kHz from clock 50, the maximum slope of the adaptive gain function ranges from 125 dB/sec to 8000 dB/sec. For a step change of 32 dB, this corresponds to a typical range of time constant from 256 milliseconds to four milliseconds respectively. If dm is set to zero, the adaptive compression feature is disabled.

FIG. 2 discloses a circuit 60 which has a number of common circuit elements with circuit 10 of FIG. 1. Such common elements have similar functions and have been marked with common reference numbers. In addition to circuit 10, however, circuit 60 of FIG. 2 provides for a programmable compression ratio. Circuit 60 has a gain control 66 which is connected to a register 62 by a line 64 and to gain register 24 by a line 68. Register 62 stores a compression factor. Gain control 66 takes the value stored in gain register 24 to the power of the compression ratio stored in register 62 and outputs said power gain value via a line 70 to an amplifier 72. Amplifier 72 combines the power gain value on line 70 with the gain value stored in a register 74 to produce an output gain on a line 76. An amplifier 78 receives the output gain via line 76 for controlling the gain of amplifier 78. Amplifier 78 amplifies the signal from input 12 accordingly. The output signal from amplifier 78 is peak clipped by a limiter 80 and supplied as an output signal for circuit 60 at an output 82 in accordance with the invention.

To summarize the operation of circuit 60, the input to limiter 80 is generated by amplifier 78 whose gain is programmably set as a power of the gain setting stored in gain register 24, while the input to comparator 32 continues to be generated as shown in circuit 10 of FIG. 1. Further, one of the many known functions other than the power function could be used for programmably setting the gain of amplifier 78.

The improvement in circuit 60 of FIG. 2 over circuit 10 of FIG. 1 is seen in FIG. 3 which shows the input/output curves for compression ratios ranging from zero through two. The curve corresponding to a compression ratio of one is the single input/output curve provided by circuit 10 in FIG. 1. Circuit 60 of FIG. 2, however, is capable of producing all of the input/output curves shown in FIG. 3.

In practice, circuit 10 of FIG. 1 or circuit 60 of FIG. 2 may be used in several parallel channels, each channel filtered to provide a different frequency response. Narrow band or broad band filters may be used to provide maximum flexibility in fitting the hearing aid to the patient's hearing deficiency. Broad band filters are used if the patient prefers one hearing aid characteristic at low input signal levels and another characteristic at high input signal levels. Broad band filters can also provide different spectral shaping depending on background noise level. The channels are preferably constructed in accordance with the filter/limit/filter structure disclosed in U.S. Pat. No. 5,111,419 (hereinafter "the '419 patent") and incorporated herein by reference.

FIG. 4 shows a 4-channel filter/limit/filter structure for circuit 10 of FIG. 1. While many types of filters can be used for the channel filters of FIG. 4 and the other Figs., FIR filters are the most desirable. Each of the filters F1, F2, F3 and F4 in FIG. 4 are symmetric FIR filters which are equal in length within each channel. This greatly reduces phase distortion in the channel output signals, even at band edges. The use of symmetric filters further requires only about one half as many registers to store the filter co-efficients for a channel, thus allowing a simpler circuit implementation and lower power consumption. Each channel response can be programmed to be a band pass filter which is contiguous

with adjacent channels. In this mode, filters F1 through F4 have preset filter parameters for selectively passing input 12 over a predetermined range of audible frequencies while substantially attenuating any of input 12 not occurring in the predetermined range. Likewise, channel filters F1 through F4 can be programmed to be wide band to produce overlapping channels. In this mode, filters F1 through F4 have preset filter parameters for selectively altering input 12 over substantially all of the audible frequency range. Various combinations of these two cases are also possible. Since the filter coefficients are arbitrarily specified, in-band shaping is applied to the band-pass filters to achieve smoothly varying frequency gain functions across all four channels. An output 102 of a circuit 100 in FIG. 4 provides an adaptively compressed and filtered output signal comprising the sum of the filtered signals at outputs 30 in each of the four channels identified by filters F1 through F4.

FIG. 5 shows a four channel filter/limit/filter circuit 110 wherein each channel incorporates circuit 60 of FIG. 2. An output 112 in FIG. 5 provides a programmably compressed and filtered output signal comprising the sum of the filtered signals at outputs 82 in each of the four channels identified by filters F1 through F4.

The purpose of the adaptive gain factor in each channel of the circuitry of FIGS. 4 and 5 is to maintain a specified constant level of envelope compression over a range of inputs. By using adaptive compressive gain, the input/output function for each channel is programmed to include a linear range for which the signal envelope is unchanged, a higher input range over which the signal envelope is compressed by a specified amount, and the highest input range over which envelope compression increases as the input level increases. This adaptive compressive gain feature adds an important degree of control over mapping a widely dynamic input signal into the reduced auditory range of the impaired ear.

The design of adaptive compressive gain circuitry for a hearing aid presents a number of considerations, such as the wide dynamic range, noise pattern and bandwidth found in naturally occurring sounds. Input sounds present at the microphone of a hearing aid vary from quiet sounds (around 30 dB SPL) to those of a quiet office area (around 50 dB SPL) to much more intense transient sounds that may reach 100 dB SPL or more. Sound levels for speech vary from a casual vocal effort of a talker at three feet distance (55 dB SPL) to that of a talker's own voice which is much closer to the microphone (80 dB SPL). Therefore, long term averages of speech levels present at the microphone vary by 25 dB or more depending on the talker, the distance to the talker, the orientation of the talker and other factors. Speech is also dynamic and varies over the short term. Phoneme intensities vary from those of vowels, which are the loudest sounds, to unvoiced fricatives, which are 12 dB or so less intense, to stops, which are another 18 dB or so less intense. This adds an additional 30 dB of dynamic range required for speaking. Including both long-term and short-term variation, the overall dynamic range required for speech is about 55 dB. If a talker whispers or is at a distance much greater than three feet, then the dynamic range will be even greater.

Electronic circuit noise and processing noise limit the quietest sounds that can be processed. A conventional hearing aid microphone has an equivalent input noise figure of 25 dB SPL, which is close to the estimated 20 dB noise figure of a normal ear. If this noise figure is used as a lower bound on the input dynamic range and 120 dB SPL is used as an upper bound, the input dynamic range of good hearing aid system is about 100 dB. Because the microphone will begin to saturate at 90 to 100 dB SPL, a lesser dynamic range of 75 dB is workable.

Signal bandwidth is another design consideration. Although it is possible to communicate over a system with a bandwidth of 3 kHz or less and it has been determined that 3 kHz carries most of the speech information, hearing aids with greater bandwidth result in better articulation scores. Skinner, M. W. and Miller, J. D., *Amplification Bandwidth and Intelligibility of Speech in Quiet and Noise for Listeners with Sensorineural Hearing Loss*, 22:253-79 *Audiology* (1983). Accordingly, the embodiment disclosed in FIG. 1 has a 6 kHz upper frequency cut-off.

The filter structure is another design consideration. The filters must achieve a high degree of versatility in programming bandwidth and spectral shaping to accommodate a wide range of hearing impairments. Further, it is desirable to use shorter filters to reduce circuit complexity and power consumption. It is also desirable to be able to increase filter gain for frequencies of reduced hearing sensitivity in order to improve signal audibility. However, studies have shown that a balance must be maintained between gain at low frequencies and gain at high frequencies. It is recommended that the gain difference across frequency should be no greater than 30 dB. Skinner, M. W., *Hearing Aid Evaluation*, Prentice Hall (1988). Further, psychometric functions often used to calculate a "prescriptive" filter characteristic are generally smooth, slowly changing functions of frequency that do not require a high degree of frequency resolution to fit.

Within the above considerations, it is preferable to use FIR filters with transition bands of 1000 Hz and out of band rejection of 40 dB. The required filter length is determined from the equation:

$$L = ((-20 \log_{10}(\sigma) - 7.95)(14.36TB/f_s)) + 1 \quad (10)$$

In equation (10), L represents the number of filter taps, σ represents the maximum error in achieving a target filter characteristic, $-20 \log_{10}(\sigma)$ represents the out of band rejection in decimals, TB represents the transition band, and f_s is the sampling rate. See Kaiser, *Nonrecursive Filter Design Using the I₀-SINH Window Function*, Proc., IEEE Int. Symposium on Circuits and Systems (1974). For an out of band rejection figure of 35 dB with a transition band of 1000 Hz and a sampling frequency of 16 kHz, the filter must be approximately 31 taps long. If a lower out of band rejection of 30 dB is acceptable, the filter length is reduced to 25 taps. This range of filter lengths is consistent with the modest filter structure and low power limitations of a hearing aid.

All of the circuits shown in FIGS. 1 through 9 use log encoded data. See the '419 patent. Log encoding is similar to u-law and A-law encoding used in Codecs and has the same advantages of extending the dynamic range, thereby making it possible to reduce the noise floor of the system as compared to linear encoding. Log encoding offers the additional advantage that arithmetic operations are performed directly on the log encoded data. The log encoded data are represented in the hearing aid as a sign and magnitude as follows:

$$x = sgn(y) \log(|y|)/\log(B) \quad (11)$$

In equation (11), B represents the log base, which is positive and close to but less than unity, x represents the log value and y represents the equivalent linear value. A reciprocal relation for y as a function of x follows:

$$y = sgn(x)B^{|x|} \quad (12)$$

If x is represented as sign and an 8-bit magnitude and the log base is 0.941, the range of y is ± 1 to $\pm 1.8 \times 10^{-7}$. This

corresponds to a dynamic range of 134 dB. The general expression for dynamic range as a function of the log base B and the number of bits used to represent the log magnitude value N follows:

$$\text{dynamic range (dB)} = 20 \log_{10}(B^{(2^N-1)}) \quad (13)$$

An advantage of log encoding over u-law encoding is that arithmetic operations are performed directly on the encoded signal without conversion to another form. The basic FIR filter equation, $y(n) = \sum a_i x(n-i)$, is implemented recursively as a succession of add and table lookup operations in the log domain. Multiplication is accomplished by adding the magnitude of the operands and determining the sign of the result. The sign of the result is a simple exclusive-or operation on the sign bits of the operands. Addition (and subtraction) are accomplished in the log domain by operations of subtraction, table lookup, and addition. Therefore, the sequence of operations required to form the partial sum of products of the FIR filter in the log domain are addition, subtraction, table lookup, and addition.

Addition and subtraction in the log domain are implemented by using a table lookup approach with a sparsely populated set of tables T_+ and T_- stored in a memory (not shown). Adding two values, x and y, is accomplished by taking the ratio of the smaller magnitude to the larger and adding the value from the log table T_+ to the smaller. Subtraction is similar and uses the log table T_- . Since x and y are in log units, the ratio, $|y/x|$ (or $|x/y|$), which is used to access the table value, is obtained by subtracting $|x|$ from $|y|$ (or vice-versa). The choice of which of the tables, T_+ or T_- , to use is determined by an exclusive-or operation on the sign bits of x and y. Whether the table value is added to x or to y is determined by subtracting $|x|$ from $|y|$ and testing the sign bit of the result.

Arithmetic roundoff errors in using log values for multiplication are not significant. With an 8-bit representation, the log magnitude values are restricted to the range 0 to 255. Zero corresponds to the largest possible signal value and 255 to the smallest possible signal value. Log values less than zero cannot occur. Therefore, overflow can only occur for the smallest signal values. Product log values greater than 255 are truncated to 255. This corresponds to a smallest signal value (255 LU's) that is 134 dB smaller than the maximum signal value. Therefore, if the system is scaled by setting the amplifier gains so that 0 LU corresponds to 130 dB SPL, the truncation errors of multiplication (255 LU) correspond to -134 dB relative to the maximum possible signal value (0 LU). In absolute terms, this provides a -4 dB SPL or -43 dB SPL spectrum level, which is well below the normal hearing threshold.

Roundoff errors of addition and subtraction are much more significant. For example, adding two numbers of equal magnitude together results in a table lookup error of 2.4%. Conversely, adding two values that differ by three orders of magnitude results in an error of 0.1%. The two tables, T_+ and T_- , are sparsely populated. For a log base of 0.941 and table values represented as an 8-bit magnitude, each table contains 57 nonzero values. If it is assumed that the errors are uniformly distributed (that each table value is used equally often on the average), then the overall average error associated with table roundoff is 1.01% for T_+ and 1.02% for T_- .

Table errors are reduced by using a log base closer to unity and a greater number of bits to represent log magnitude. However, the size of the table grows and quickly becomes impractical to implement. A compromise solution for reducing error is to increase the precision of the table entries without increasing the table size. The number of

nonzero entries increases somewhat. Therefore, in implementing the table lookup in the digital processor, two additional bits of precision are added to the table values. This is equivalent to using a temporary log base which is the fourth root of 0.941 (0.985) for calculating the FIR filter summation. The change in log base increases the number of nonzero entries in each of the tables by 22, but reduces the average error by a factor of four. This increases the output SNR of a given filter by 12 dB. The T_+ and T_- tables are still sparsely populated and implemented efficiently in VLSI form.

In calculating the FIR equation, the table lookup operation is applied recursively $N-1$ times, where N is the order of the filter. Therefore, the total error that results is greater than the average table roundoff error and a function of filter order. If it is assumed that the errors are uniformly distributed and that the input signal is white, the expression for signal to roundoff noise ratio follows:

$$\epsilon_y^2 \sigma_y^2 = \epsilon^2(c_1^2 + 2c_2^2 + \dots + (N-1)c_{N-1}^2)(c_1^2 + c_2^2 + \dots + c_N^2) \quad (14)$$

In equation (14) ϵ_y^2 represents the noise variance at the output of the filter σ_y^2 represents the signal variance at the output of the filter, and ϵ represents the average percent table error. Accordingly, the filter noise is dependent on the table lookup error, the magnitude of the filter coefficients, and the order of summation. The coefficient used first introduces an error that is multiplied by $N-1$. The coefficient used second introduces an error that is multiplied by $N-2$ and so on. Since the error is proportional to coefficient magnitude and order of summation, it is possible to minimize the overall error by ordering the smallest coefficients earliest in the calculation. Since the end tap values for symmetric filters are generally smaller than the center tap value, the error was further reduced by calculating partial sums using coefficients from the outside toward the inside.

In FIGS. 4 and 5, FIR filters F1 through F4 represent channel filters which are divided into two cascaded parts. Limiters 26 and 80 are implemented as part of the log multiply operation. G_1 is a gain factor that, in the log domain, is subtracted from the samples at the output of the first FIR filter. If the sum of the magnitudes is less than zero (maximum signal value), it is clipped to zero. G_2 represents an attenuation factor that is added (in the log domain) to the clipped samples. G_2 is used to set the maximum output level of the channel.

Log quantizing noise is a constant percentage of signal level except for low input levels that are near the smallest quantizing steps of the encoder. Assuming a Laplacian signal distribution, the signal to quantizing noise ratio is given by the following equation:

$$SNR(\text{dB}) = 10 \log_{10}(12) - 20 \log_{10}(\ln(B)) \quad (15)$$

For a log base of 0.941, the SNR is 35 dB. The quantizing noise is white and, since equation (15) represents the total noise energy over a bandwidth of 8 kHz, the spectrum level is 39 dB less or 74 dB smaller than the signal level. The ear inherently masks the quantizing noise at this spectrum level. Schroeder, et al., *Optimizing Digital Speech Coders by Exploiting Masking Properties of the Human Ear*, Vol. 66(6) J. Acous. Soc. Am. pp. 1647-52 (December 1979). Thus, log encoding is ideally suited for auditory signal processing. It provides a wide dynamic range that encompasses the range of levels of naturally occurring signals, provides sufficient SNR that is consistent with the limitation of the ear to resolve small signals in the presence of large signals, and provides a significant savings with regard to hardware.

The goal of the fitting system is to program the digital hearing aid to achieve a target real-ear gain. The real-ear gain is the difference between the real-ear-aided-response (REAR) and the real-ear-unaided-response (REUR) as measured with and without the hearing aid on the patient. It is assumed that the target gain is specified by the audiologist or calculated from one of a variety of prescriptive formulae chosen by the audiologist that is based on audiometric measures. There is not a general consensus about which prescription is best. However, prescriptive formulae are generally quite simple and easy to implement on a small host computer. Various prescriptive fitting methods are discussed in Chapter 6 of Skinner, M. W., *Hearing Aid Evaluation*, Prentice Hall (1988).

Assuming that a target real-ear gain has been specified, the following strategy is used to automatically fit the four channel digital hearing aid where each channel is programmed as a band pass filter which is contiguous with adjacent channels. The real-ear measurement system disclosed in U.S. Pat. No. 4,548,082 (hereinafter "the '082 patent") and incorporated herein by reference is used. First, the patient's REUR is measured to determine the patient's normal, unoccluded ear canal resonance. Then the hearing aid is placed on the patient. Second, the receiver and earmold are calibrated. This is done by setting G_2 of each channel to maximum attenuation (-134 dB) and turning on the noise generator of the adaptive feedback equalization circuit shown in the '082 patent. This drives the output of the hearing aid with a flat-spectrum-level, pseudorandom noise sequence. The noise in the ear canal is then deconvolved with the pseudorandom sequence to obtain a measure of the output transfer characteristic (H_r) of the hearing aid. Third, the microphone is calibrated. This is done by setting the channels to a flat nominal gain of 20 dB. The cross-correlation of the sound in the ear canal with the reference sound then represents the overall transfer characteristic of the hearing aid and includes the occlusion of sound by the earmold. The microphone calibration (H_m) is computed by subtracting H_r from this measurement. Last, the channel gain functions are specified and filter coefficients are computed using a window design method. See Rabiner and Schafer, *Digital Processing of Speech Signals*, Prentice Hall (1978). The coefficients are then downloaded in bit-serial order to the coefficient registers of the processor. The coefficient registers are connected together as a single serial shift register for the purpose of downloading and uploading values.

The channel gains are derived as follows. The acoustic gain for each channel of the hearing aid is given by:

$$\text{Gain} = H_m + H_r + H_n + G_{1n} + G_{2n} \quad (16)$$

The filter shape for each channel is determined by setting the Gain in equation (16) to the desired real-ear gain plus the open-ear resonance. Since G_{1n} and G_{2n} are gain constants for the channel and independent of frequency, they do not enter into the calculation at this point. The normalized filter characteristics is determined from the following equation.

$$H_n = 0.5 (\text{Desired Real-ear gain} + \text{open ear cal} - H_m - H_r + G_n) \quad (17)$$

H_m and H_r represent the microphone and receiver calibration measures, respectively, that were determined for the patient with the real ear measurement system and G_n represents a normalization gain factor for the filter that is included in the computation of G_{1n} and G_{2n} . H_m and H_r include the transducer transfer characteristics in addition to the frequency response of the amplifier and any signal conditioning filters.

13

Once H_n is determined, the maximum output of each channels which is limited by L, are represented by G_{2n} as follows:

$$G_{2n} = MPO_n - L - \text{avg}(H_n + H_r) - G_n \quad (18)$$

In equation (18), the "avg" operator gives the average of filter gain and receiver sensitivity at filter design frequencies within the channel. L represents a fixed level for all channels such that signals falling outside the range $\pm L$ are peak-clipped at $\pm L$. G_n represents the filter normalization gain, and MPO_n represents the target maximum power output. Overall gain is then established by setting G_{1n} as follows:

$$G_{1n} = 2G_n - G_{2n} \quad (19)$$

G_n represents the gain normalization factor of the filters that were designed to provide the desired linear gain for the channel.

By using the above approach, target gains typically are realized to within 3 dB over a frequency range of from 100 Hz to 6000 Hz. The error between the step-wise approximation to the MPO function and the target MPO function is also small and is minimized by choosing appropriate crossover frequencies for the four channels.

Because the channel filters are arbitrarily specified, an alternative fitting strategy is to prescribe different frequency-gain shapes for signals of different levels. By choosing appropriate limit levels in each channel, a transition from the characteristics of one channel to the characteristics of the next channel will occur automatically as a function of signal level. For example, a transparent or low-gain function is used for high-level signals and a higher-gain function is used for low-level signals. The adaptive gain feature in each channel provides a means for controlling the transition from one channel characteristic to the next. Because of recruitment and the way the impaired ear works, the gain functions are generally ordered from highest gain for soft sounds to the lowest gain for loud sounds. With respect to circuit 100 of FIG. 4, this is accomplished by setting G1 in gain register 22 very high for the channel with the highest gain for the soft sounds. The settings for G1 in gain registers 22 of the next succeeding channels are sequentially decreased, with the G1 setting being unity in the last channel which has the lowest gain for loud sounds. A similar strategy is used for circuit 110 of FIG. 5, except that G1 must be set in both gain registers 22 and 74. In this way, the channel gain settings in circuits 100 and 110 of FIGS. 4 and 5 are sequentially modified from first to last as a function of the level of input 12.

The fitting method is similar to that described above for the four-channel fitting strategy. Real-ear measurements are used to calibrate the ear, receivers and microphone. However, the filters are designed differently. One of the channels is set to the lowest gain function and highest ACG threshold. Another channel is set to a higher-gain function, which adds to the lower-gain function and dominates the spectral shaping at signal levels below a lower ACG threshold setting for that channel. The remaining two channels are set to provide further gain contributions at successively lower signal levels. Since the channel filters are symmetric and equal length, the gains will add in the linear sense. Two channels set to the same gain function will provide 6 dB more gain than either channel alone. Therefore, the channels filters are designed as follows:

$$H_1 = \frac{1}{2} D_1 \quad (20)$$

$$H_2 = \frac{1}{2} \log_{10} (10^{D_2} - 10^{D_1}) \quad (21)$$

14

$$H_3 = \frac{1}{2} \log_{10} (10^{D_3} - 10^{D_2} - 10^{D_1}) \quad (22)$$

$$H_4 = \frac{1}{2} \log_{10} (10^{D_4} - 10^{D_3} - 10^{D_2} - 10^{D_1}) \quad (23)$$

where: $D_1 < D_2 < D_3 < D_4$. D_n represents the filter design target in decibels that gives the desired insertion gain for the hearing aid and is derived from the desired gains specified by the audiologist and corrected for ear canal resonance and receiver and microphone calibrations as described previously for the four-channel fit. The factor, $\frac{1}{2}$, in the above expressions takes into account that each channel has two filters in cascade.

The processor described above has been implemented in custom VLSI form. When operated at 5 volts and at a 16-kHz sampling rate, it consumes 4.6 mA. When operated at 3 volts and at the same sampling rate, it consumes 2.8 mA. When the circuit is implemented in a low-voltage form, it is expected to consume less than 1 mA when operated from a hearing aid battery. The processor has been incorporated into a bench-top prototype version of the digital hearing aid.

Results of fitting hearing-impaired subjects with this system suggest that prescriptive frequency gain functions are achieved within 3 dB accuracy at the same time that the desired MPO frequency function is achieved within 5 dB or so of accuracy.

For those applications that do not afford the computational resources required to implement the circuitry of FIGS. 1 through 5, the simplified circuitry of FIGS. 6 through 9 is used. In FIG. 6, a circuit 120 includes an input 12 which represents any conventional source of an input signal such as a microphone, signal processor, or the like. Input 12 also includes an analog to digital converter (not shown) for analog input signals if circuit 120 is implemented with digital components. Likewise, input 12 includes a digital to analog converter (not shown) for digital input signals if circuit 120 is implemented with analog components.

Input 12 is connected to a group of filters F1 through F4 and a filter S1 over a line 122. Filters F1 through F4 provide separate channels with filter parameters preset as described above for the multichannel circuits of FIGS. 4 and 5. Each of filters F1, F2, F3 and F4 outputs an adaptively filtered signal via a line 124, 126, 128 and 130 which is amplified by a respective amplifier 132, 134, 136 and 138. Amplifiers 132 through 138 each provide a channel output signal which is combined by a line 140 to provide an adaptively filtered signal at an output 142 of circuit 120.

Filter S1 has parameters which are set to extract relevant signal characteristics present in the input signal. The output of filter S1 is received by an envelope detector 144 which detects said characteristics. Detector 144 preferably has a programmable time constant for varying the relevant period of detection. When detector 144 is implemented in analog form, it includes a full wave rectifier and a resistor/capacitor circuit (not shown). The resistor, the capacitor, or both, are variable for programming the time constant of detector 144. When detector 144 is implemented in digital form, it includes an exponentially shaped filter with a programmable time constant. In either event, the "on" time constant is shorter than the relatively long "off" time constant to prevent excessively loud sounds from existing in the output signal for extended periods.

The output of detector 144 is a control signal which is transformed to log encoded data by a log transformer 146 using standard techniques and as more fully described above. The log encoded data represents the extracted signal characteristics present in the signal at input 12. A memory 148 stores a table of signal characteristic values and related amplifier gain values in log form. Memory 148 receives the

log encoded data from log transformer 146 and, in response thereto, recalls a gain value for each of amplifiers 132, 134, 136 and 138 as a function of the log value produced by log transformer 146. Memory 148 outputs the gain values via a set of lines 150, 152, 154 and 156 to amplifiers 132, 134, 136 and 138 for setting the gains of the amplifiers as a function of the gain values. Arbitrary overall gain control functions and blending of signals from each signal processing channel are implemented by changing the entries in memory 148.

In use, circuit 120 of FIG. 6 may include a greater or lesser number of filtered channels than the four shown in FIG. 6. Further, circuit 120 may include additional filters, detectors and log transformers corresponding to filter S1, detector 144 and log transformer 146 for providing additional input signal characteristics to memory 148. Still further, any or all of the filtered signals in lines 124, 126, 128 or 130 could be used by a detector(s), such as detector 144, for detecting an input signal characteristic for use by memory 148.

FIG. 7 includes input 12 for supplying an input signal to a circuit 160. Input 12 is connected to a variable filter 162 and to a filter S1 via a line 164. Variable filter 162 provides an adaptively filtered signal which is amplified by an amplifier 166. A limiter 168 peak clips the adaptively filtered output signal of amplifier 166 to produce a limited output signal which is filtered by a variable filter 170. The adaptively filtered and clipped output signal of variable filter 170 is provided at output 171 of circuit 160.

Filter S1, a detector 144 and a log transformer 146 in FIG. 7 perform similar functions to the like numbered components found in FIG. 6. A memory 162 stores a table of signal characteristic values, related filter parameters, and related amplifier gain values in log form. Memory 162 responds to the output from log transformer 146 by recalling filter parameters and an amplifier gain value as functions of the log value produced by log transformer 146. Memory 162 outputs the recalled filter parameters via a line 172 and the recalled gain value via a line 174. Filters 162 and 170 receive said filter parameters via line 172 for setting the parameters of filters 162 and 170. Amplifier 166 receives said gain value via line 174 for setting the gain of amplifier 166. The filter coefficients are stored in memory 162 in sequential order of input signal level to control the selection of filter coefficients as a function of input level. Filters 162 and 170 are preferably FIR filters of the same construction and length and are set to the same parameters by memory 162. In operation, the circuit 160 is also used by taking the output signal from the output of amplifier 166 to achieve desirable results. Limiter 168 and variable filter 170 are shown, however, to illustrate the filter/limit/filter structure disclosed in the '419 patent in combination with the pair of variable filters 162 and 170.

With a suitable choice of filter coefficients, a variety of level dependent filtering is achieved. When memory 162 is a random-access memory, the filter coefficients are tailored to the patient's hearing impairment and stored in the memory from a host computer during the fitting session. The use of the host computer is more fully explained in the '082 patent.

A two channel version of circuit 120 in FIG. 6 is shown in FIG. 8 as circuit 180. Like components of the circuits in FIGS. 6 and 8 are identified with the same reference numerals. A host computer (such as the host computer disclosed in the '082 patent) is used for calculating the F1 and F2 filter coefficients for various spectral shaping, for calculating entries in memory 148 for various gain functions and blending functions, and for down-loading the values to the hearing aid.

The gain function for each channel is shown in FIG. 9. A segment "a" of a curve G1 provides a "voice switch" characteristic at low signal levels. A segment "b" provides a linear gain characteristic with a spectral characteristic determined by filter F1 in FIG. 8. A segment "c" and "d" provide a transition between the characteristics of filters F1 and F2. A segment "e" represents a linear gain characteristic with a spectral characteristic determined by filter F2. Lastly, segment "f" corresponds to a region over which the level of output 142 is constant and independent of the level of input 12.

The G1 and G2 functions are stored in a random access memory such as memory 148 in FIG. 8. The data stored in memory 148 is based on the specific hearing impairment of the patient. The data is derived from an appropriate algorithm in the host computer and down-loaded to the hearing aid model during the fitting session. The coefficients for filters F1 and F2 are derived from the patients residual hearing characteristic as follows: Filter F2, which determines the spectral shaping for loud sounds, is designed to match the patients UCL function. Filter F1, which determines the spectral shaping for softer sounds, is designed to match the patients MCL or threshold functions. One of a number of suitable filter design methods are used to compute the filter coefficient values that correspond to the desired spectral characteristic.

A Kaiser window filter design method is preferable for this application. Once the desired spectral shape is established, the filter coefficients are determined from the following equation:

$$C_n = \sum A_k (\cos(2\pi n f_s / f_k)) W_n \quad (24)$$

In equation (24), C_n represents the n'th filter coefficient, A_k represents samples of the desired spectral shape at frequencies f_k , f_s represents the sampling frequency and W_n represents samples of the Kaiser Window. The spectral sample points, A_k , are spaced at frequencies, f_k , which are separated by the 6 dB bandwidth of the window, W_n , so that a relatively smooth filter characteristic results that passes through each of the sample values. The frequency resolution and maximum slope of the frequency response of the resulting filter is determined by the number of coefficients or length of the filter. In the implementation shown in FIG. 8, filters F1 and F2 have a length of 30 taps which, at a sampling rate of 12.5 kHz, gives a frequency resolution of about 700 Hz and a maximum spectral slope of 0.04 dB/Hz.

Circuit 180 of FIG. 8 simplifies the fitting process. Through a suitable interactive display on a host computer (not shown), each spectral sample value A_k is independently selected. While wearing a hearing aid which includes circuit 180 in a sound field, such as speech weighted noise at a given level, the patient adjusts each sample value A_k to a preferred setting for listening. The patient also adjusts filter F2 to a preferred shape that is comfortable only for loud sounds.

Appendix A contains a program written for a Macintosh host computer for setting channel gain and limit values in a four channel contiguous band hearing aid. The filter coefficients for the bands are read from a file stored on the disk in the Macintosh computer. An interactive graphics display is used to adjust the filter and gain values.

In view of the above, it will be seen that the several objects of the invention are achieved and other advantageous results attained.

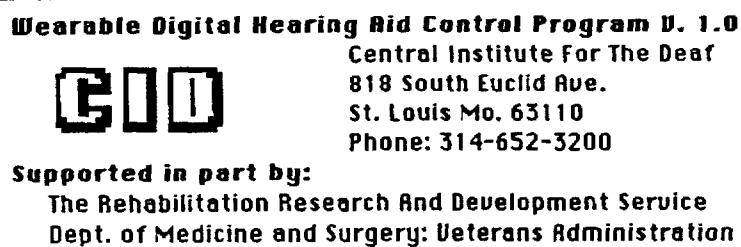

As various changes could be made in the above constructions without departing from the scope of the invention, it is intended that all matter contained in the above description or shown in the accompanying drawings shall be interpreted as illustrative and not in a limiting sense.

Program WDHA

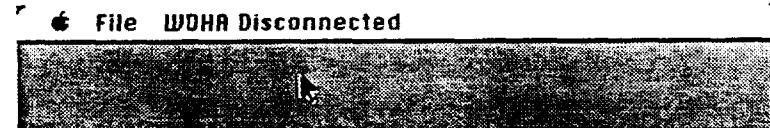

General Overview

A program entitled "WDHA" has been written for the Macintosh personal computer. When a wearable digital hearing aid is attached to the Macintosh's SCSI bus peripheral interface, the user of the WDHA program can alter the operation of the hearing aid via an easy to use Macintosh style user interface.

Using the WDHA Program

Starting The Program

Upon starting the program, the Macintosh interrogates the hearing aid to determine which program it is running. If the hearing aid responds appropriately, a menu containing the options which apply to that particular program appears in the menu bar. If no response is received from the hearing aid, the menu entitled "WDHA Disconnected" appears in the menu bar, as follows:

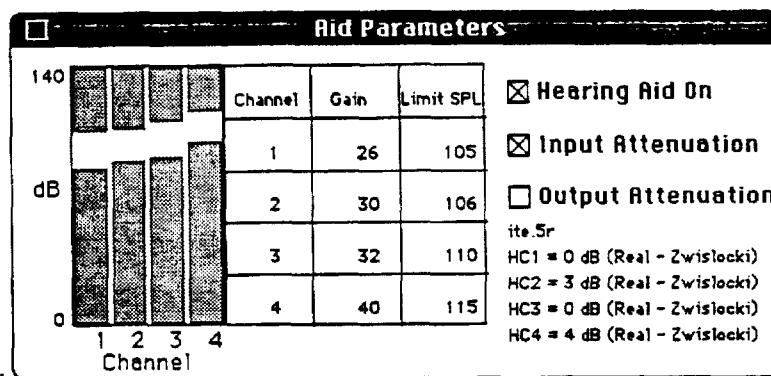

Should this menu appear, this indicates that there is some problem with the hearing aid. The source of this problem could be that the hearing aid is truly disconnected, that it is simply turned off, or that the hearing aid battery is dead. Upon correcting the problem,

choose the "New WDHA Program" menu entry to activate the proper menu for the hearing aid.

The Aid Parameters Window

The four channel hearing aid programs have the titles Aid12 through Aid14. Choosing the "Aid Parameters" menu entry will cause the aid parameters window to be displayed, as follows:

The bar graph and chart depict the current settings of the gains and limits for each channel of the hearing aid. A gain or limit setting can be changed by dragging the appropriate bar up or down with the mouse. The selected bar will blink when it is activated, and can be moved until the mouse is released, at which point the hearing aid is updated with the new values.

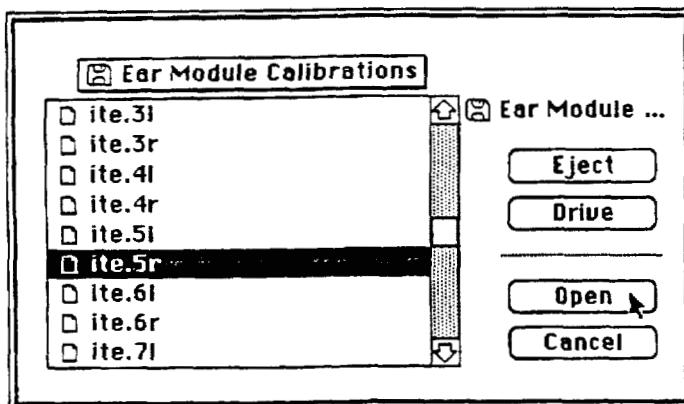

The control buttons indicate whether the hearing aid is on or off (i.e. whether the hearing aid program is running), and whether the input or output attenuators are switched on or off. Any of these settings can be changed simply by clicking on the appropriate buttons.

Ear Module Calibration

The File menu has an option called "Calibrate Ear Module" which should be used whenever the program is started or an ear module is inserted (or re-inserted) in a patient's ear. Proper use of

this option insures that the gains actually generated by the hearing aid are as close to the gains indicated by the program as possible.

The lower right hand corner of the Aid Parameters window displays the results of the most recent ear module calibration, including the name of the calibration file and the four Hc values, where Hc is the difference between the real ear pressure measured in the ear canal and the standard pressure measured on a Zwislocki at the center frequency of each channel. After choosing this option the user must open the file containing the ear module coefficients, by double clicking on the file's name, via a standard Macintosh dialog box:

The program will then play a series of four tones in the patient's ear, using the power measurement to determine the real pressure in the ear canal.

The file containing the ear module coefficients should be created with a text editor and saved as a text-only file. The file contains all the H values for a given ear module, separated by tabs, spaces, or carriage returns. It should begin with the four He values, followed by the Hr values, then Hc, and then Hp. The values entered for the Hc values can be arbitrary, since the program calculates them and stores them into the file. An ear module file as you would enter it might look as follows:

```
-100 -85 -90 -84 121 116 127 120
0
0
```

```

0
0
-124 -121 -134 -143

```

Here the first row contains both the four He values and the four Hr values. Following this are four zeros (since the Hc values are unknown). The sixth row contains the Hp values. Note that values are arbitrarily separated by tabs, spaces, or carriage returns.

After doing an ear module calibration with the program, the new Hc values are displayed in the Aid Settings window, and also written to the same file, with the data re-formatted into a separate row for each H value, as follows:

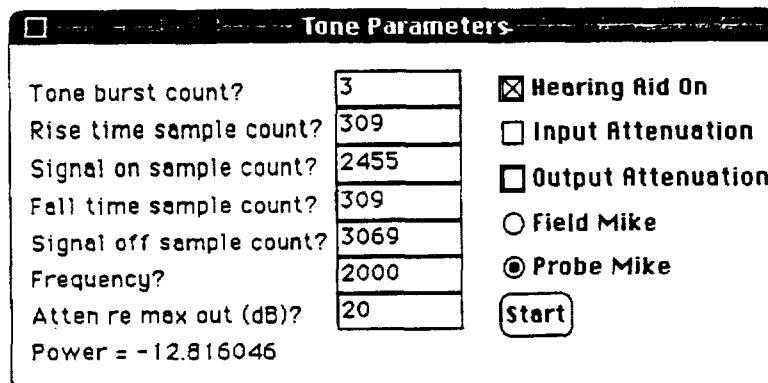

```

-100 -85 -90 -84
121 116 127 120
-5 -4 -10 0
-124 -121 -134 -143

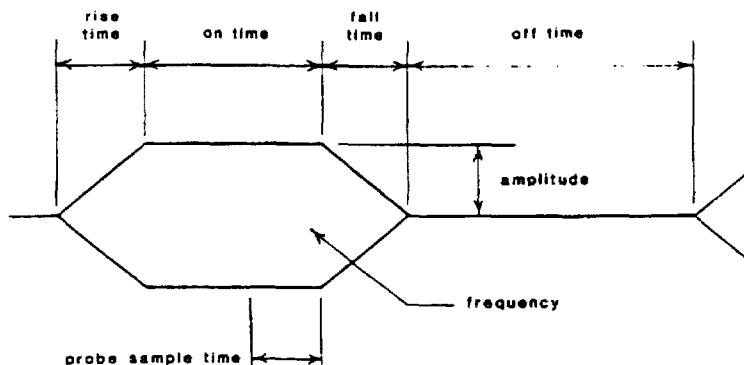

```

The Tone Parameters Window

The four channel programs also have the ability to play pure tones for audiometric purposes. The Tone Parameters window is available to activate these functions. Choosing the "Tone Parameters" menu entry will cause the Tone Parameters window to be displayed, as follows:

The text boxes specify the number of tone bursts to generate and the envelope of the tone bursts generated, as follows:

All times are specified in number of sample periods, and cannot exceed 32767 sample periods. The test is initiated by clicking on the start button. The control buttons act just as in the aid parameters window.

• Loading Filter Taps

The programs titled Aid13 and Aid14 have the capability to download filter tap coefficients to the hearing aid. The coefficients are read into memory from a text file which the user creates with any standard text editor. The coefficients in these files are signed integers such as "797" or "-174" (optionally be followed by a divisor, such as in "-12028/2") and must be separated by spaces, tabs, or carriage returns.

The Aid13 program has 32 taps per filter, and the Aid14 program has 31 taps per filter, but since the filters are symmetric about the center tap you only provide half this number of taps, or 16 taps per filter. Thus the files contain 64 coefficients for the 4 channels. For example, the file titled TapsFour has the following format:

```
-535/4 -431/4 -254/4 0 333/4 743/4 1220/4 1750/4
2315/4 2892/4 3545/4 3977/4 4432/4 4797/4 5052/4 5183/4
-34/2 -231/2 -223/2 0 292/2 398/2 77/2 -745/2
-1873/2 -2869/2 -3212/2 -2535/2 -831/2 1483/2 3683/2 5021/2
-83/2 502/2 859/2 0 -1128/2 -866/2 189/2 128/2
-442/2 890/2 3076/2 1605/2 -3814/2 -6280/2 -922/2 6543/2
```

528/2 -167/2 -446/2 0 585/2 288/2 -1203/2 242/2
 442/2 1525/2 -2946/2 797/2 -174/2 6280/2 -12028/2 6482/2

The option to download coefficients is enabled by choosing the "Tap Filter Load" menu entries. The Macintosh will then present the standard open file dialog box, which you use to specify the name of the appropriate text file.

Program Design

The program is written in 68000 Assembly Language using the Macintosh Development System assembler, from Apple.

The program has been structured into separate managers for each of the program's functions. A separate file contains the functions associated with each manager. For example, the Parameter Settings (or "PS") manager is contained in the file WDHAPS.Asm, and includes all routines associated with the Aid Parameters window.

Below is a description of each manager, it's function, and the routines contained in each.

WDHA.Asm

The overall program structure is typical of a Macintosh application in that it has an event loop which dequeues events from the event queue, and then branches to code which processes each particular type of event. WDHA.Asm contains the WDHA program's event loop.

WDHAPS.Asm

The Parameter Settings ("PS") manager contains all routines associated with the Aid Parameters window, which allows the user to control the gains and limits of each of the channels in the four channel programs. Specifically, these routines are as follows:

- WDHAPSSOpen - Create and display the Aid Parameters window.
- WDHAPSClose - Close the Aid Parameters window and dispose the memory associated with it.
- WDHAPSShow - Make the Aid Parameters window visible.
- WDHAPSHide - Make the Aid Parameters window invisible.
- WDHAPSDraw - Update the contents of the Aid Parameters window.

WDHAPSControl - Cause the appropriate modification of the Aid Parameters window when a mousedown event occurs within its content region.

WDHAPSIS - Given a window pointer, this routine determines if it is the Aid Parameters window or not.

WDHAPSSetParam - Update the hearing aid to contain the settings specified in the Aid Parameters window.

WDHATC.Asm

The TC manager contains all routines associated with the Tone Parameters window, which allows the user to specify the parameters for the test/calibrate function of the four channel program, and initiate the test. Specifically, these routines are as follows:

WDHATCOpen - Create and display the Tone Parameters window.

WDHATCClose - Close the Tone Parameters window and dispose the memory associated with it.

WDHATCShow - Make the Tone Parameters window visible.

WDHATCHide - Make the Tone Parameters window invisible.

WDHATCDraw - Update the contents of the Tone Parameters window.

WDHATCControl - Cause the appropriate modification of the Tone Parameters window when a mousedown event occurs within its content region.

WDHATCIS - Given a window pointer, this routine determines if it is the Tone Parameters window or not.

WDHATCIdle - Blink the text caret of the Tone Parameters window.

WDHATCKey - Insert a key press into the active text box of the Tone Parameters window.

WDHATCDoTest - Initiate a test by the hearing aid program, using the parameters specified by the Tone Parameters window.

EarModuleCalibrate - Compute the Hc values for each of the four channels (this routine uses the test/calibrate function of the hearing aid to figure the real ear pressure at the center frequency of each channel).

WDHASCSI.Asm

The SCSI manager contains all routines which send record structures to the hearing aid via the SCSI bus.

SetParam - Send the four channel parameter record (containing the gains and limits) to the four channel hearing aid program.

SetCoefficients - Send out the filter tap coefficients to the four channel hearing aid program.

SetFileParams - Send the parameters required by the spectral shaping program.

wdhatest - Initiate a pure tone test by sending the test/calibrate record to the hearing aid.

WDHAFC.Asm

The WDHA program accesses some numerical values it needs by reading them in from text files. The File Coefficients (FC) manager contains routines which access these text files.

WDHAFCSet - This routine is called when the user selects the "Load Filter Taps" menu option. It uses the SFGetFile dialog to get the name of a text file containing filter coefficients, convert the contents to integer form, and then downloads them to the hearing aid.

WDHASEtFileParams - This routine is used to download parameters to the Spectral Shaping hearing aid program. It uses the SFGetFile dialog to get the name of a text file containing the spectral shaping parameters, converts the contents to integer form, then downloads them to the hearing aid.

WDHACalEarModFile - This routine is called when the user calibrates the ear module. It uses the SFGetFile dialog to get the name of a text file containing ear module H Tables, and converts its contents to integer form in memory. Then it calibrates the ear module using the TC manager function EarModuleCalibrate. Finally, it writes the new H Tables over the same file.

WDHAMenu.Asm

The Menu manager contains all routines associated with the WDHA program's menu bar.

MakeMenus - Create the Menu bar containing the accessory, file, and hearing aid menus, and display it on the screen.

MenuBar - When the main event loop gets a mouseDown event located in the menu Bar, this routine calls the appropriate code to handle the selection.

SetProgMenu - This routine interrogates the hearing aid to determine which program it is currently running, then places the appropriate menu in the menu bar.

Programmer's Note -

As explained earlier, the WDHA program has separate pulldown menus defined for each program which runs on the hearing aid, giving the options available for that particular program. It is not difficult to add a new menu to the hearing aid program. The following example shows the steps one would follow to add a new aid menu (in this case 'Aid17') to the menu bar.

First of all, the constants needed for the menu must be defined with equate statements. You must define the code returned by the aid program when it is interrogated by the Macintosh, the identifier for the menu itself (as required by the NewMenu toolbox function), and the offset within the menu handles declarations where this handle will reside (the handles are defined in a sequential block of memory near the end of the Menu.Asm file).

```
Aid17ID    equ  -17 ; aid program id returned by interrogating the
aid.
Aid17Menu   equ  17 ; Unique menu identifier
menuaid17 equ  40 ; 10*4=menuhandle offset (this is the tenth
handle)
```

Next you would declare the location to store the menu's handle at the end of the menu handles declarations:

```
dc.l 0          ; Aid17 menu handle
```

Next one would add code to the MakeMenus routine to create the new menu (simply cut and paste the code which creates one of the current menus and modify it accordingly).

You would also modify the SetProgMenu routine to handle the new menu (once again simply replicate the code sections which handle one of the old menus, and change the menu names appropriately).

Finally, you would modify the MenuBar routine to handle your new menu. If all the options contained in your menu are also in the

other hearing aid menus, you can call the InAidMenu procedure (as the other menus do), otherwise you must define your own procedure to call.

WDHADisk.Asm

The disk manager contains routines used to access disk files on the Macintosh.

- DiskCreate - Create a new file.
- DiskRead - Read sectors from a file.
- DiskWrite - Write sectors to a file.
- DiskEject - Eject a disk.
- DiskOpen - Open a file.
- DiskClose - Close a file
- DiskSetFPos - Set the position of a file's read/write mark.
- DiskSetEOF - Set the location of the end of file marker for a file.
- DiskSetFInfo - Set the finder information for a file.

;-----
; WDHA Parameter Settings Window Manager
; This package contains routines to manipulate the WDHA Parameter
; Settings window. This window contains an interface which controls the
; gain and limit of each channel of the WDHA by allowing the user to move
; bars on a graph of Frequency versus dB SPL (execute the program for a better
; understanding), this control is referred to as the "PSGraph" in the program
; documentation. Next to this graph is a chart (the "PSChart") containing the
; numeric values of each channel's gain and limit.
; It also contains control buttons to specify if the WDHA should be in
; Hearing aid mode, if the input attenuation should be off or on, and whether
; the aid should use the probe mike or the field mike. The output attenuation
; is automatically turned on or off by the program, it's control being used
; as an indicator of this status.
; Wherever the documentation refers to the term "theta", it is referring
; to the height of the lower bar of the bar graph, and wherever the documentation
; uses "phi", it refers to the height of the upper bar.

; file WDGHAFC.Asm
; This file contains two routines which read text files containing
; numeric expressions, and download the numbers to the digital hearing
; aid. The routine WDHAFCSet is used in the Aid13 program to download
; filter tap coefficients to the hearing aid. The routine WDHASetFileParams
; is used to download parameters for the SS15 spectral shaping program.
; The text files accessed by these routines must contain integer numbers
; separated by any character which is nonnumeric and not '-' (generally spaces,
; tabs, or carriage returns). The text files accessed by WDHAFCSet can also
; contain simple numeric expressions of the form A/B, where A and B are
; integers.

What is claimed is:

1. An adaptive gain amplifier circuit comprising:
an amplifier for receiving an input signal in the audible frequency range and producing an output signal;
means for establishing a threshold level for the output signal;
a comparator for producing a control signal as a function of the level of the output signal being greater or less than the threshold level; 10
- a gain register for storing a gain setting;
an adder responsive to the control signal for increasing the gain setting up to a predetermined limit when the output signal falls below the threshold level and for decreasing the gain setting when the output signal rises above the threshold level; and 15
- a preamplifier having a preset gain for amplifying the gain setting to produce a gain signal;
wherein the amplifier is responsive to the preamplifier for varying the gain of the amplifier as a function of the gain signal.
wherein the output signal is adaptively compressed. 20
2. The circuit of claim 1 wherein the adder comprises means for increasing the gain setting in increments having a first preset magnitude and for decreasing the gain setting in decrements having a second preset magnitude. 25
3. The circuit of claim 1 further comprising means for producing a timing sequence wherein the gain register is enabled in response to the timing sequence for receiving the gain setting from the adder during a predetermined portion of the timing sequence. 30
4. The circuit of claim 1 wherein the adder further comprises a secondary register for storing a first and second preset magnitude and wherein the adder is responsive to the secondary register for increasing the gain setting in increments corresponding to the first preset magnitude and for decreasing the gain setting in decrements corresponding to the second preset magnitude. 35
5. The circuit of claim 1 further comprising means for clipping the adaptively compressed output signal at a predetermined level and for producing an adaptively clipped compressed output signal. 40
6. A programmable compressive gain amplifier circuit comprising:
a first amplifier for receiving an input signal in the audible frequency range and for producing an amplified signal;
means for establishing a threshold level for the amplified signal; 45
- a gain register for storing a gain value;
means, responsive to the amplified signal and the threshold level, for increasing the gain value when the amplified signal falls below the threshold level and for decreasing the gain value when the amplified signal rises above the threshold level; 50
- wherein the first amplifier is responsive to the gain register for varying the gain of the first amplifier as a function of the gain value; 55
- a second amplifier for receiving the input signal and for producing an output signal; and
means for programming the gain of the second amplifier as a function of the gain value.
wherein the output signal is programmably compressed. 60
7. The circuit of claim 6 wherein the increasing and decreasing means comprises means for increasing the gain 65

196

value in increments having a first preset magnitude and for decreasing the gain value in decrements having a second preset magnitude.

8. The circuit of claim 7 wherein the increasing and decreasing means further comprises:
a comparator for producing a control signal as a function of the level of the amplified signal being greater or less than the threshold level; and
an adder responsive to the control signal for increasing the gain value by the first preset magnitude when the amplified signal falls below the threshold level and for decreasing the gain value by the second preset magnitude when the amplified signal rises above the threshold level, wherein the first amplifier is responsive to the gain register for varying the gain of the first amplifier as a function of the gain value. 10
9. The circuit of claim 8 wherein the increasing and decreasing means further comprises means for producing a timing sequence wherein the gain register is enabled in response to the timing sequence for receiving the gain value from the adder during a predetermined portion of the timing sequence. 15
10. The circuit of claim 8 wherein the increasing and decreasing means further comprises a secondary register for storing the first and second preset magnitudes and wherein the adder is responsive to the secondary register for increasing the gain value in increments corresponding to the first preset magnitude and for decreasing the gain value in decrements corresponding to the second preset magnitude. 20
11. The circuit of claim 6 wherein the means for programming comprises means for varying the gain of the second amplifier as a function of a power of the gain value. 25
12. The circuit of claim 11 wherein the means for programming further comprises a register for storing a power value and wherein the programming means varies the gain of the second amplifier as a function of the value derived by raising the gain value to the power of the stored power value. 30
13. The circuit of claim 6 wherein the first and second amplifiers each comprise a two stage amplifier, the first stage having a variable gain and the second stage having a preset gain. 35
14. The circuit of claim 6 further comprising means for clipping the programmably compressed output signal at a predetermined level and for producing a programmably clipped and compressed output signal. 40
15. An adaptive gain amplifier circuit comprising:
an amplifier for receiving an input signal in the audible frequency range and producing an output signal;
a gain register for storing a gain value;
a preamplifier having a preset gain for amplifying the gain value to produce a gain signal;
wherein the amplifier is responsive to the preamplifier for varying the gain of the amplifier as a function of the gain signal;
means for establishing a threshold level for the output signal; and 45
- means, responsive to the output signal and the threshold level, for increasing the gain value up to a predetermined limit when the output signal falls below the threshold level and for decreasing the gain value when the output signal rises above the threshold level.
wherein the output signal is adaptively compressed. 50
16. The circuit of claim 15 wherein the increasing and decreasing means comprises:
a comparator for producing a control signal as a function of the level of the output signal being greater or less than the threshold level; and 55

197

an adder responsive to the control signal for increasing the gain value when the output signal falls below the threshold level and for decreasing the gain value when the output signal rises above the threshold level.

17. The circuit of claim 16 wherein the increasing and decreasing means further comprises means for producing a timing sequence, said increasing and decreasing means being enabled in response to the timing sequence for increasing or decreasing the gain value during a predetermined portion of the timing sequence. 10

18. The circuit of claim 16 wherein the increasing and decreasing means further comprises a secondary for storing a first and second preset magnitude and wherein the adder is responsive to said secondary register for receiving the first and second preset magnitudes for increasing and decreasing 15 the gain value.

19. The circuit of claim 15 wherein the increasing and decreasing means further comprises means for increasing the gain value in increments having a first preset magnitude and for decreasing the gain value in decrements having a 20 second preset magnitude.

20. The circuit of claim 15 further comprising means for clipping the output signal at a predetermined level and for producing an adaptively clipped compressed output signal.

21. An adaptive gain amplifier circuit comprising:

an amplifier for receiving an input signal in the audible frequency range and producing an output signal; means for establishing a threshold level for the output signal;

a gain register for storing a gain value; and

means, responsive to the output signal and the threshold level, for increasing the gain value in increments having a first preset magnitude when the output signal falls below the threshold level and for decreasing the gain value in decrements having a second preset magnitude when the output signal rises above the threshold level; wherein the gain register stores the gain value as a first plurality of least significant bits and as a second plurality of most significant bits;

wherein the first preset magnitude comprises a number of bits less than or equal to a total number of bits comprising the least significant bits;

wherein the gain register outputs the most significant bits of the gain value to the amplifier for controlling the gain of the amplifier; and

wherein the output signal is compressed as a function of the ratio of the second preset magnitude over the first preset magnitude to produce an adaptively compressed 45 output signal.

22. The circuit of claim 21 further comprising a register for storing the first and second preset magnitudes, the register having six bits of memory for storing the first preset magnitude and six bits of memory for storing the second preset magnitude. 50

23. The circuit of claim 21 further comprising a register for storing the first and second preset magnitudes; wherein the register stores both said magnitudes in logarithmic form.

24. The circuit of claim 23 further comprises a limiter for limiting the adaptively compressed output signal; wherein the limiter clips a constant percentage of the adaptively compressed output signal. 60

25. The circuit of claim 21 wherein the gain register stores the gain value in logarithmic form; and wherein the increas-

198

ing and decreasing means increases and decreases the gain value in constant percentage amounts.

26. An adaptive gain amplifier circuit comprising a plurality of channels connected to a common output, each channel comprising:

a filter with preset parameters for receiving an input signal in the audible frequency range for producing a filtered signal;

a channel amplifier responsive to the filtered signal for producing a channel output signal;

a channel gain register for storing a gain value;

a channel preamplifier having a preset gain for amplifying the gain value to produce a gain signal;

wherein the channel amplifier is responsive to the channel preamplifier for varying the gain of the channel amplifier as a function of the gain signal;

means for establishing a channel threshold level for the channel output signal; and

means, responsive to the channel output signal and the channel threshold level, for increasing the gain value up to a predetermined limit when the channel output signal falls below the channel threshold level and for decreasing the gain value when the channel output signal rises above the channel threshold level;

wherein the channel output signals are combined to produce an adaptively compressed and filtered output signal.

27. An adaptive gain amplifier circuit comprising:

a plurality of channels connected to a common output, each channel comprising:

a filter with preset parameters for receiving an input signal in the audible frequency range and for producing a filtered signal;

a channel amplifier responsive to the filtered signal for producing a channel output signal;

means for establishing a channel threshold level for the channel output signal;

a comparator for producing a control signal as a function of the level of the channel output signal being greater or less than the channel threshold level;

a channel gain register for storing a gain setting;

an adder responsive to the control signal for increasing the gain setting by a first preset magnitude when the channel output signal falls below the channel threshold level and for decreasing the gain setting by a second preset magnitude when the channel output signal rises above the channel threshold level; and

a second channel gain register for storing a predetermined channel gain value to define an operating range for the channel as a function of a signal level of the input signal;

wherein the channel amplifier is responsive to the gain register and to the second channel gain register for varying the gain of the channel amplifier as a function of the gain setting and the predetermined channel gain value; and

wherein the channel output signals are combined to produce an adaptively compressed and filtered output signal.

UNITED STATES PATENT AND TRADEMARK OFFICE
CERTIFICATE OF CORRECTION

PATENT NO. : 5,724,433

DATED : March 3, 1998

INVENTOR(S) : A. Maynard Engebretson et al.

It is certified that error appears in the above-identified patent and that said Letters Patent is hereby corrected as shown below:

Column 196, claim 10, line 25, "register for for" should read
---register for---.

Column 196, claim 12, line 34, "programing means" should read
---means for programming---.

Column 197, claim 18, line 12, "secondary for storing" should read
---secondary register for storing---.
